ABSTRACT
The pipeline is a fundamental pattern to parallelize a series of stage tasks over a sequence of data in loops. Mainstream pipeline programming frameworks count on data abstractions to perform pipeline scheduling. Although this design is convenient for data-centric parallel applications, it is not efficient for algorithms that only exploit task parallelism in the pipeline. To address the limitation, we introduce a new task-parallel pipeline programming framework called Pipeflow. Pipeflow separates data abstractions and task scheduling, enabling a more efficient implementation of task-parallel pipeline algorithms than existing frameworks. We have evaluated Pipeflow on both micro-benchmarks and real-world applications. For example, in a timing analysis workload that explores pipeline parallelism to speed up the runtime performance, the Pipeflow’s implementation outperforms the oneTBB’s implementation up to 110.33% faster.

ACM Reference Format:

1 INTRODUCTION
The pipeline is a fundamental parallel pattern to model parallel executions through a linear chain of stages. Each stage processes a data token after the previous stage, applies an abstract function to that token, and then resolves the dependency for the next stage.

Multiple data tokens can be processed simultaneously across different stages whenever dependencies are met. For example, in circuit simulation [26, 35–37], some operations on a gate (e.g., NAND, OR, AND) do not depend on other gates and thus can be done at multiple logic levels simultaneously, while operations at the same levels require processing prior levels first. As pipeline parallelism widely exists in modern computing applications [5], there is always a need for new pipeline programming frameworks to streamline the implementation complexity of pipeline algorithms.

Recently, several pipeline programming frameworks have emerged to assist developers in implementing pipeline algorithms without worrying about scheduling details, such as oneTBB [1], FastFlow [4], GrPPI [13], Cilk-P [50], SPAR [15], and HPX-pipeline [46]. While each of these frameworks has its pros and cons, a common design philosophy is to perform data synchronizations using buffers between stages (i.e., data abstraction) in their pipeline scheduling designs, as illustrated in Figure 1. This design is convenient for data-centric pipeline applications but also has two limitations. Firstly, users have to design their pipeline algorithms in the data-parallel manner. However, data management is often application-dependent. Many applications exhibit pipeline parallelism among tasks rather than data. For example, the VLSI timing analysis application [9, 10] formulates a sequence of linearly dependent propagation tasks in a graph node and runs independent nodes in parallel to efficiently update the timing data from a custom global shared graph data structure. The real need is a pipeline scheduling framework to schedule and run tasks while leaving data management completely to applications.

Figure 1: An illustration of data abstraction in a pipeline framework. Gray bars are buffers used for data synchronizations.

Secondly, scheduling algorithms involve complex synchronizations between data and buffer structures. These frameworks typically leverage object allocators and buffer structures to manage temporary data between stages (e.g., oneTBB [1]). However, the synchronizations can be redundant in some applications. For instance, ferret [5], a pipeline benchmark of PARSEC, defines six stages (loading, segmentation, extraction, indexing, ranking, and output) in its...
We first review the pipeline basics and then detail the motivation of a new task-parallel pipeline programming framework. We summarize our contributions as follows:

- **Task-Parallel Pipeline.** We have introduced a new task-parallel pipeline programming concept that separates task scheduling and data abstraction. This separation allows us to concentrate on the pipeline tasking itself, enabling a more efficient implementation of task-parallel pipeline algorithms than existing frameworks.

- **Programming Model.** We have introduced a new C++ programming model to support our concept. Unlike existing models, we do not provide yet another data abstraction but a flexible framework for users to fully control their application data atop a task-parallel pipeline scheduling framework.

- **Scheduling Algorithm.** We have introduced a new scheduling algorithm to schedule stage tasks across parallel lines. Since we do not touch data abstraction, we can avoid complex data buffer designs and synchronization mechanisms to enable more lightweight and efficient scheduling.

We have evaluated Pipeflow on both micro-benchmarks and real-world applications. For example, in a real-world VLSI static timing analysis workload, the Pipeflow implementation outperforms the oneTBB implementation up to 110.3% faster. Right now, Pipeflow is merged into the open-source Taskflow project.

## 2 BACKGROUND

We first review the pipeline basics and then detail the motivation of Pipeflow. We then argue a new task-parallel pipeline programming model is needed for many important industrial and research areas, e.g., circuit design.

### 2.1 Pipeline Basics

Pipeline parallelism is commonly used to parallelize various applications, such as stream processing, video processing, and dataflow systems. These applications exhibit parallelism in the form of a linear pipeline, where a linear sequence of abstraction functions, namely stages, $F = (f_1, f_2, \cdots, f_i)$, is applied to an input sequence of data tokens, $D = (d_1, d_2, \cdots, d_i)$. A linear pipeline can be thought of as a loop over the data tokens of $D$. Each iteration $i$ processes an input token $d_i$ by applying the stage functions $F$ to $d_i$ in order. Depending on the number of parallel lines, $L = (l_1, l_2, \cdots, l_L)$, to process data tokens, parallelism arises when iterations overlap in time. For instance, the execution of token $d_i$ at stage $f_j$ of parallel line $l_k$, denoted as $f^j_k(d_i)$, can overlap with $f^{j+1}_k(d_{i+1})$. A stage can be a parallel type or a serial type to specify whether $f^j_k(d_i)$ can overlap with $f^{j+1}_k(d_{i+1})$ or not. Figure 2 shows the dependency diagram of a 3-stage (serial-serial-parallel) pipeline.

![Figure 2: Dependency diagram of a 3-stage (serial-serial-parallel) pipeline. Each node represents a task that applies a stage function to a data token. Each edge represents a dependency between two tasks. The dashed rectangle denotes one parallel line.](image)

### 2.2 Task-parallel Pipeline Parallelism

Pipeflow is motivated by our research projects on developing parallel timing analysis algorithms for very large scale integration (VLSI) computer-aided design (CAD) [17, 18, 20, 21, 25, 26, 75]. Timing analysis is a critical step in the overall CAD flow because it validates the timing performance of a digital circuit. As design complexity continues to grow exponentially, the need to efficiently analyze the timing has become the major bottleneck to the design closure flow. For instance, generating a comprehensive timing report (e.g., pessimism removal, hundreds of corners, etc.) for a multi-million-gate design can take several hours [45]. To reduce the analysis runtime, there is an increasing trend of adopting manycore parallelism by new timing analysis algorithms recently [8, 19, 22, 27, 38–41, 44, 54, 59].

![Figure 3: Parallel timing propagations. Linearly dependent timing data (e.g., slew) is updated across graph nodes in a task-parallel pipeline fashion.](image)
propagation tasks, including parasitics (RCP), slew (SLP), delay (DLP), arrival time (ATP), jump points (JMP), and common path pessimism reduction (CRP) to update its timing data from a custom global and application-dependent circuit graph data structure. Different propagation tasks can overlap across different levels using pipeline parallelism.

This type of task-parallel pipeline strategy is ubiquitous in many parallel CAD algorithms, such as logic simulation [49, 58] and physical design [29, 30, 32, 48], because computations frequently flow through circuit networks. We have observed three important properties that make mainstream pipeline programming frameworks fall short of our needs: 1) Unlike the typical data-parallel pipeline, the pipeline parallelism in many CAD algorithms is driven by tasks rather than data. 2) Data is not directly involved in the pipeline but in the graph data structure defined by a custom algorithm. 3) From a user’s standpoint, the real need is a pipeline scheduling framework to help schedule and run tasks on input tokens across parallel lines while leaving data management completely to applications; in our experience, users disfavor another library data abstraction to perform pipeline scheduling, as it often incurs development inconvenience and unnecessary data conversion overheads.

3 PIPEFLOW

Inspired by the need for parallel CAD algorithms, Pipeflow introduces a new task-parallel pipeline programming model for users to create a pipeline scheduling framework without data abstraction. In this section, we will dive into the technical details of Pipeflow.

3.1 Programming Model

Pipeflow leverages modern C++ and template techniques to strike a balance between expressiveness and generality. Listing 1 shows the Pipeflow code that implements the pipeline in Figure 2. Pipeflow has one API Pipeline that allows users to define the pipeline structure and explore the pipeline parallelism in their applications. There are two steps to create a Pipeflow application, 1) define the pipeline structure using template instantiation using the Pipeline API and 2) define the application data storage, if needed. In Pipeflow, the terms "pipe" and "stage" are interchangeable. For the first step, users define the number of parallel lines and the abstract function of each pipe in a Pipeline object. For each pipe, users define the pipe type and a pipe callable using Pipe. A pipe can be either a serial type (PipeType::SERIAL) or a parallel type (PipeType::PARALLEL). The pipe callable takes an argument of Pipeline type, which is created by the scheduler at runtime. A Pipeflow object pf represents a scheduling token and contains several methods for users to query the runtime statistics of that token, including the parallel line, pipe, and token numbers.  

```
const size_t num_lines = 4;
std::variant<float, std::string> data_type;
std::array<

const size_t num_lines = 4;
std::variant<float, std::string> data_type;
std::array<

const size_t num_lines = 4;
std::variant<float, std::string> data_type;
std::array<

const size_t num_lines = 4;
std::variant<float, std::string> data_type;
std::array<

Listing 1: Pipeflow code of Figure 2, assuming the first pipe generates float and the second pipe generates string outputs.

Pipeflow does not have any data abstraction but gives applications full control over data management. In our example, since the first and the second pipes generate float and std::string outputs, respectively, we create a one-dimensional (1D) array, buffer, as the application data storage to store data in uniform storage using std::variant<float, std::string>. The dimension of the array is equal to the number of parallel lines, as Pipeflow schedules only one token per parallel line. Each entry buffer[i] stores the data that is being processed at parallel line i, which can be retrieved by Pipeflow::line. This organization is space-efficient because we use only a 1D array to represent data processing in a two-dimensional (2D) scheduling map. Additionally, by delegating data management to applications, we can avoid dynamic data conversion between the library and the application, which typically counts on virtual function calls to convert a generic type (e.g., void*, std::any) to an arbitrary user type [1, 4].

Based on the pipeline structure and data layout defined above, we instantiate a Pipeline object, pl. This template-based design enables the compiler to optimize each pipe type, such as using a fixed-layout functor to store the callable and its captured data. Finally, we call run to submit the object pl to a runtime and execute it.

Using P = Pipe<

Listing 2: Scalable pipeline model in Pipeflow to accept variable assignments of pipes.

Pipeflow requires instantiation of all pipes at the construction time. While this design gives compilers more freedom to optimize the layout of each pipe type, it prevents applications from varying the pipeline structure at runtime; for instance, the number of pipes might depend on the problem size, which can be runtime variables. To overcome this limitation, Pipeflow provides a scalable alternative, ScalablePipeline, to allow variable assignments of pipes using
range iterators. In Listing 2, we create a scalable pipeline, pipel, from a vector of six pipes p. After the first run, we reset p to another range of three pipes for the second run. A scalable pipeline is thus more flexible for applications to create a pipeline scheduling framework with dynamic structures.

Compared to the programming model of existing frameworks, such as oneTBB [1], Pipel’s programming model has the following advantages: 1) Pipeflow is expressive and easy to write. Users only need pipe type, pipe callable, and the number of parallel lines to create a pipeline scheduling framework and explore the pipeline parallelism in their applications. Moreover, as Pipeflow does not provide data abstraction, users do not need to explicitly specify the input data and output data type at every pipe definition as oneTBB’s users do. 2) Pipeflow is flexible. Users are able to modify the pipeline structure at runtime based on their specific needs.

3.2 Scheduling Algorithm

![Diagram of scheduling task-parallel pipeline](image)

Figure 4: The scheduling diagram of the task-parallel pipeline in Listing 1. Each parallel line runs one scheduling token. Multiple parallel lines overlap tokens in a circular fashion. The text “token (4t+0) on pipe 1, line 1” means the token with ID 4t+0 runs on the pipe 1 and the parallel line 1.

As Pipeflow does not touch data abstraction, we can simplify the pipeline scheduling problem to decide which scheduling token to run at which pipe and parallel line. Our scheduling algorithm places only one scheduling token per parallel line. We then process all tokens in a circular fashion across the given number of parallel lines. Figure 4 illustrates our pipeline scheduling idea using the pipeline in Listing 1. Since the pipeline schedules tokens in a circular fashion, there are four edges (dependencies) from the last pipes (p1 2) to the first pipes (p1 0), and one edge from the first pipe of the last parallel line to the first pipe of the first parallel line. The last pipe (p1 2) is a parallel type. There is no vertical edge between the last pipes of two consecutive parallel lines. Each parallel line runs only one scheduling token. Multiple parallel lines can overlap tokens whenever their dependencies are met. Even though the pipeline execution can involve many scheduling tokens, only four parallel lines are used in total.

3.3 Pseudocode

```
Algorithm 1: define_task()
  global: pipeflows: a vector of Pipeflow objects
  global: join_counters: a 2D array of join counters
  global: num_tokens: the number of tokens
  global: num_lines: the number of parallel lines
  global: num_pipes: the number of pipes

  Input: l: a parallel line id
  pf ← pipeflows[l];
  AtomicStore(join_counters[pf.line][pf.pipe], pf.join_counter);

  if pf.pipe == 0 then
    pf.token ← num_tokens;
    invoke_pipe_callable(pf);
    if pf.stop == True then
      return;
  end

  if pf.pipe != 0 then
    invoke_pipe_callable(pf);
  end

  curr_pipe ← pf.pipe;
  next_pipe ← (pf.pipe + 1)%num_pipes;
  next_line ← (pf.line + 1)%num_lines;
  pf.pipe ← next_pipe;
  next_tasks = {};

  if curr_pipe is SERIAL and
    AtomicDecrement(join_counters[pf.line][curr_pipe]) == 0 then
    next_tasks.insert(1);
  end

  if next_tasks.size == 2 then
    call_scheduler(task_of_next_line);
    goto Line 2;
  end

  if next_tasks.size == 1 then
    if next_tasks[0] == 1 then
      pf ← pipeflows[next_line];
    end
    goto Line 2;
  end
```

Based on the idea discussed in Section 3.2, we formulate each parallel line as a task, which defines a function object to run by a
thread in the thread pool. Each task 1) deals with one scheduling token per parallel line and 2) decides which adjacent task to run on its next parallel line and pipe. Algorithm 1 implements such a task using efficient atomic operations. When a task is scheduled, we need to know which pipe at which parallel line for the scheduling token to work. We keep the parallel line and pipe information in a Pipeflow object. Each task owns a Pipeflow object pf of a specific parallel line (line 1). Once a scheduling token is done, there are two cases for its corresponding task to proceed: 1) for a parallel type, the task moves to the next pipe at the same parallel line; 2) for a serial type, the task additionally checks if it can move to the next parallel line. To carry out such a dependency constraint, each pipe keeps a join counter of an atomic integer to represent its dependency value. The values of a serial pipe and a parallel pipe can be up to 2 and 1, respectively. We create a 2D array join_counters to store the join counter of each pipe at each parallel line. Line 2 initializes these join counters to either 2 or 1 based on the corresponding pipe types that are enumerated on integer constants, 2 (serial) and 1 (parallel). At the first pipe (line 3), the Pipeflow object updates its token number (line 4) and checks if the pipe callable requests to stop the pipeline (lines 5:8). If continued, we increment the number of scheduled tokens by one (line 9). For other pipes, we simply invoke the pipe callables (lines 11:13).

After the pipe callable returns, we update the join counters based on the pipe type and determine the next possible tasks to run (lines 14:24). When the join counter of a pipe becomes 0, we bookmark this pipe as a task to run next (line 20 and line 23). If two tasks exist (line 25), the current task informs the scheduler to call a worker thread to run the task at the next parallel line (line 26) and reiterates itself on the next pipe (line 27). The idea here is to facilitate data locality as applications tend to deal with the next pipe at the same parallel line as soon as possible. If there is only one task available, the current task directly runs the next task with the updated pf object (lines 29:34).

Compared to existing algorithms, such as oneTBB [1], that count on non-trivial synchronization between tasks and internal data buffers, our algorithm focuses on the task parallelism of a pipeline itself. This design largely reduces the scheduling complexity of pipeline by using lightweight atomic operations without complex data buffer management.

3.4 Proof

We draw the following lemmas and sketch their proofs to highlight the correctness of our scheduling algorithm:

**Lemma 1.** Only one task runs a pipe callable (line 5 and line 12 in Algorithm 1) on a scheduling token.

**Proof.** Assume two tasks are running the same pipe callable, which means one task reiterates its execution from the previous pipe, and the other task comes from the previous parallel line. This is not possible in a parallel pipe as there is no dependency from the previous parallel line; only one runtime task decrements the join counter to 0 (line 22 in Algorithm 1). Take Figure 4 for example. There is no vertical edge pointing to token 4t+1 from token 4t+0 for pipe 2. Only the task that runs token 4t+1 on pipe 1 gets to decrement the join counter for task 4t+1 on pipe 2. In a serial pipe, this is also not possible because the dependency is resolved using atomic operations; only one task will acquire the zero value of the join counter (line 19 in Algorithm 1). For example, in Figure 4, either the task running token 4t+0 on pipe 1 or the task running token 4t+1 on pipe 0 decrements token 4t+1 on pipe 1 to zero and then runs the pipe. □

**Lemma 2.** The scheduler does not miss any pipe.

**Proof.** We consider the situation where one task moves to the next parallel line (line 31 in Algorithm 1) instead of the next pipe at the same parallel line. Under this circumstance, we need to make sure one task will run that next pipe. Take Figure 4 for example. Suppose a task finishes token 4t+1 at pipe 0 and precedes to token 4t+2 at pipe 0, meaning that the join counter of token 4t+1 at pipe 1 is not 0 yet. Another task that works on token 4t+0 at pipe 1 will eventually decrement the join counter to run it (line 27 in Algorithm 1) or invoke another worker thread to run it (line 26 in Algorithm 1). □

4 EXPERIMENTAL RESULTS

We implemented Pipeflow using C++17 and evaluated the performance of Pipeflow on a micro-benchmark and a real-world industrial CAD application. We studied the performance across memory (RSS), runtime, and throughput. We did not use conventional pipeline benchmarks (e.g., PARSEC’s ferret[5] has only six pipes, loading, segmentation, extraction, indexing, ranking, and output) as their problem sizes are relatively small compared to CAD, and the runtime difference between Pipeflow and the baseline is not obvious on small pipelines. We compiled all programs using g++12 with -std=c++17 and -O3 enabled. We ran all the experiments on a Ubuntu Linux 19.10 (Eoan Ermine) machine with 40 Intel Xeon Gold 6138 CPU cores at 2.00 GHz and 256 GB RAM. All data is an average of ten runs.

4.1 Baseline

Given a large number of pipeline programming frameworks, it is infeasible to compare Pipeflow with all of them. We considered oneTBB [1] as our baseline for two reasons. First, oneTBB is the only library that provides a single pipeline API for users to explore pipeline parallelism. Others require combining several library-specific constructs to achieve this goal. For example, in Cilk-P users need pipe_while, pipe_stage, and pipe_stage_wait to add pipeline parallelism in applications. Second, Pipeflow is inspired by our CAD applications, and oneTBB is widely used in the CAD community due to its absolute speed and robustness. For a fair comparison, we implemented the same work-stealing strategy as oneTBB in our thread pool, in particular, call_scheduler in line 26 in Algorithm 1.

4.2 Micro-benchmark

The purpose of micro-benchmarks is to measure the pure scheduling performance without much computation bias from applications. We compared the memory, runtime, and throughput between Pipeflow and oneTBB for completing pipelines of different numbers of serial pipes, scheduling tokens, and threads. We did not use parallel pipes as their callable can be absorbed into the previous serial...
pipe. Each pipe performs a nominal work of constant space and
time complexity (e.g., small matrix multiplications) and forwards a
scheduling token to the next pipe.

Figure 5 illustrates the maximum RSS between Pipeflow and
oneTBB with different scheduling tokens and threads. The number
of parallel lines and pipes of a pipeline is equal to the number of
threads. We can see that oneTBB starts to consume more memory
than Pipeflow as we increase the pipeline size. For example, with $2^{10}$
scheduling tokens Pipeflow needs 1.97% and 11.68% less memory
than oneTBB when running with 16 and 64 threads, respectively.
The same trend is also observed in the plot of processing
124.18%, and 201.38% faster than oneTBB with 8, 16, 64, and 80
threads. As a result, the former pipeline exhibits higher task sched-
uling overhead than the latter and thus spends more time to finish.
Although the micro-benchmark only demonstrates the pure sched-
uling performance and forwards the scheduling token between
pipes, the overhead of data abstraction design of oneTBB results in
a significant runtime difference, especially in a large pipeline.

Figure 7 compares the throughput by corunning the same pro-
gram up to 8 times. Corunning a program at different configurations
is very common in some applications, such as [45]. The experiment
emulates a server-like environment where different pipeline appli-
cations compete for the same resources. We use the weighted
speedup to measure the system throughput, which is the sum of
the individual speedup of each process over a baseline execution
time[14]. A throughput of one implies that the corun throughput is
the same as if those processes run consecutively. On the left plot, the
pipeline has 16 pipes and 16 parallel lines and runs with 16 threads.
On the right plot, the pipeline has 80 pipes and 80 parallel lines and
runs with 80 threads. Both of them run $2^{15}$ scheduling tokens. We
can see that Pipeflow outperforms oneTBB in all coruns. For exam-
ple, at 8 coruns Pipeflow is 1.2x and 3.31x better than oneTBB with
16 and 80 pipes, respectively. Besides, Pipeflow remains around one
to up to 5 coruns while oneTBB decreases after 2 coruns. We attribute
the finding to the reason that we use lightweight atomic opera-
tions rather than complex data buffer synchronizations to do the
task scheduling. As Pipeflow is more lightweight than oneTBB in
pipeline scheduling, corunning Pipeflow thus has better throughput
than corunning oneTBB.

The above experiments were running with the configuration in
which the number of pipes is the same as the number of threads.
However, this configuration does not always guarantee the best
runtime performance because of different applications and hard-
ware environments. Next, we see how the number of threads could
impact the performance. Figure 8 shows the impact of Pipeflow and
oneTBB running with different numbers of threads in a small (16
pipes) and a big (80 pipes) pipeline in which $2^{10}$ and $2^{15}$ tokens
were scheduled. For 16 pipes, we can see that the runtime trends of
running $2^{10}$ and $2^{15}$ are similar. oneTBB has the best runtime
performance with 32 threads; Pipeflow has the best performance
at 16 threads. For 80 pipes, the runtime trends are the same. We
find out that Pipeflow has the best performance with 80 threads
while oneTBB with 32 threads. In this micro-benchmark, we know
the selection of identical pipes and threads is the best option for
Pipeflow but not for oneTBB. Selecting the best thread number is
an important factor and the best thread number for one application
may not be the best choice for another application.

4.3 VLSI Static Timing Analysis Algorithm
We applied Pipeflow to solve a large-scale VLSI static timing analy-
sis (STA) problem. The goal is to analyze the timing landscape of a

![Figure 5: Maximum RSS comparison between Pipeflow and
oneTBB with different scheduling tokens and threads. The number
of threads is the same as the number of pipes in the pipeline.](image)

![Figure 6: Maximum RSS comparison between Pipeflow and
oneTBB with different scheduling tokens and threads. The number
of threads is the same as the number of pipes in the pipeline.](image)
circuit design and report critical paths that do not meet the given constraints (e.g., setup and hold). As presented in Figure 3, modern STA engines leverage pipeline parallelism to speed up the timing propagations. However, nearly all of them count on OpenMP-based loop parallelism with layer-by-layer synchronization [34]. With Pipeflow, we can directly formulate the problem as a task-parallel pipeline to improve task asynchrony. As the analysis complexity continues to increase, more analysis tasks (e.g., RC, delay calculators, pessimism reduction) are incorporated into each node in the STA graph. These tasks can be encapsulated in a sequence of pipe functions to overlap in the graph across parallel lines. We modified a large circuit design of 1.5M nodes and 3.5M edges from [3, 34] and studied the performance under different pipe counts. Each node has a pipe task to calculate delay values at a specific configuration using linear interpolation. We levelized the STA graph and ran the nodes at the same level in parallel, such that different analysis tasks overlaps across different levels using pipeline parallelism, as illustrated in Figure 3.

Figure 9 evaluates the memory usage between Pipeflow and oneTBB at different graph sizes ($|V| + |E|$) and thread counts. The number of pipes and parallel lines in the pipeline is identical to the number of threads. As the pipeline size grows, the gap in memory usage starts to increase in both 1.5M and 5M graph sizes. For instance, with 1.5M graph size Pipeflow needs 0.07% and 5.6% less than oneTBB at 32 and 80 threads, respectively. We can observe a similar trend when we process 5M graph size. Since Pipeflow delegates data management directly to applications without touching data abstractions, Pipeflow does not allocate as much memory as oneTBB to perform pipeline scheduling.

Figure 10 compares the runtime performance between Pipeflow and oneTBB at different graph sizes ($|V| + |E|$) and thread counts. The number of pipes and parallel lines of the pipeline is the same as the number of threads in this experiment. We can see that Pipeflow outperforms oneTBB when we increase the graph size. Taking 16 threads for example, Pipeflow runs 62.02%, 57.44%, and 46.08% faster than oneTBB with 1, 3, and 5M graph size, respectively. The performance improvements reduce because the overhead of setting
Figure 8: Impacts of selecting the number of threads on the runtime performance for the micro-benchmark. The number of pipes is not identical to the number of threads. The numbers of pipes are 16 and 80. The pipeline processes $2^{10}$ and $2^{15}$ scheduling tokens.

reduce because the cost of data buffers is amortized gradually as the pipeline size grows. Despite the runtime improvements gradually decrease when the pipeline size grows or the graph size increases, Pipeflow still outperforms oneTBB in all cases in the workload. Since our scheduling algorithm does not deal with data passing between pipes, we can process scheduling tokens more efficiently than oneTBB. In Pipeflow all pipe tasks perform computations directly on a global graph data structure captured in the pipe callable instead of passing data between successive pipes using buffers. The data passing interface between successive pipes in oneTBB thus becomes an unnecessary overhead.

Next, we compare the throughput by corunning the same program up to 8 times. Corunning the STA program is very common for reporting the timing data of a design at different input library files[45]. The effect of pipeline scheduling propagates to all simultaneous processes. Hence, throughput is a good measurement for the inter-operability of a pipeline-based STA algorithm. We corun the same analysis program up to 8 processes that compete for 40 cores. Again, we use the weighted speedup to measure the throughput. Figure 11 plots the throughput across 8 coruns at 16 and 80 pipes. The number of pipes is identical to the number of threads. We can see that Pipeflow outperforms oneTBB at all coruns. For instance, at 8 coruns Pipeflow is 1.04x and 1.14x better than oneTBB with 16 and 80 pipes, respectively. This is because Pipeflow leverages lightweight atomic operations and oneTBB relies on complex
4.4 Importance of Task-Parallel Pipeline

As experienced parallel CAD researchers, Pipeflow has assisted us in overcoming many programming challenges. For example, in the previous experiments, the data is explicitly managed by the application algorithms and there is no need to go through any data abstraction. The real need is a task-parallel pipeline programming framework that 1) gives applications full control over data and 2) allows applications to probe each scheduled task. For instance, when implementing the STA algorithm, we captured the data from a global STA graph structure in each pipe callable and used the

Figure 11: Throughput of corunning STA programs with 16 and 80 pipes and 1.5M graph size (|V| + |E|).

So far, we ran the experiments of this workload using the number of threads same as the number of pipes. This configuration may not always give us the best runtime performance because of different hardware environment and workloads. Next, we demonstrate the importance of selecting the number of threads in this workload. Figure 12 shows the runtime performance of Pipeflow and oneTBB processing 1.5M and 5M graph size with different numbers of threads in 16-pipe and 80-pipe pipelines. For 16 pipes, we observe that both Pipeflow and oneTBB have a similar runtime trend, and both achieve the best performance with 64 threads for 1.5M graph size. With 5M graph size Pipeflow has the best performance with 80 threads while oneTBB with 64 threads. For 80 pipes, both Pipeflow and oneTBB have the best performance with 32 threads. From Figure 12 we learn that the alignment of threads and pipes does not achieve the best runtime performance in the workload. Hence, selecting the thread counts is an important factor while exploring pipeline parallelism in applications.

Figure 10: Runtime comparison between Pipeflow and oneTBB at different graph sizes (|V| + |E|) and thread counts for the timing analysis workload. The number of threads is identical to the number of pipes in the pipeline.

4.4 Importance of Task-Parallel Pipeline

As experienced parallel CAD researchers, Pipeflow has assisted us in overcoming many programming challenges. For example, in the previous experiments, the data is explicitly managed by the application algorithms and there is no need to go through any data abstraction. The real need is a task-parallel pipeline programming framework that 1) gives applications full control over data and 2) allows applications to probe each scheduled task. For instance, when implementing the STA algorithm, we captured the data from a global STA graph structure in each pipe callable and used the
Figure 12: Impacts of selecting the number of threads on the runtime performance for the timing analysis workload. The number of pipes is not identical to the number of threads. The numbers of pipes are 16 and 80. The graph sizes \((|V| + |E|)\) are 1.5M and 5M.

The \( \# \text{pipes} \times \# \text{threads} \) variable to get the parallel line number of a scheduled task to index the corresponding entry in a result vector. However, oneTBB abstracts these components out, and we have to implement another mapping strategy to get these data from each filter, both of which incur significant yet unnecessary runtime overheads. Similar situations exist in other libraries too.

### 4.5 Selection of the Number of Parallel Lines

Selecting the number of parallel lines (or threads) for the best performance is application-dependent. For example, Figure 8 illustrates that Pipellow obtains the best performance while aligning the pipe sizes and thread counts and oneTBB should run with 32 threads in the micro-benchmark. From Figure 12 when running the STA workload, both Pipellow and oneTBB obtain the best runtime results with 32 threads in an 80-pipe pipeline. From the micro-benchmark and STA algorithm, we learn that the selection of the number of parallel lines (or threads) is a critical factor regarding the runtime performance. Moreover, as the performance of an application tends to saturate or peak at a certain limit, increasing the number of parallel lines exceeds the limit could negatively affect the runtime. As a result, Pipellow makes the number of parallel lines a tunable parameter (similarly in oneTBB). Based on our experience, most applications can obtain decent performance when the number of parallel lines is equal to the number or twice the number of the cores.

### 5 RELATED WORK

Pipeline programming models. have received intensive research interest. Most of them are data-centric, using static template instantiation or dynamic runtime polymorphism to model data processing in a pipeline. To name a few popular examples: oneTBB [1] and TPL [51] require explicit definitions of input and output types for each stage; GrPPI [13] provides a composable abstraction for data- and stream-parallel patterns with a pluggable back-end to support task scheduling; FastFlow [4] models parallel dataflow using pre-defined sequential and parallel building blocks; TTG [7] focuses on dataflow programming using various template optimization techniques; SPar [15, 16, 24, 60] analyzes annotated attributes extracted from the data and stream parallelism domain, and automatically generates parallel patterns defined in FastFlow; Proteas [61] introduces a programming model for directive-based parallelization of linear pipeline; [73, 74] propose a self-adaptive mechanism to decide the degree of parallelism and generate the pattern compositions in FastFlow; OpenMP [2] uses task construct and depend clause to explore pipeline parallelism. Although these programming models are used in many applications, such as oneTBB in PARSEC [5], they constrain users to design pipeline algorithms using their data models, making it difficult to use, especially for applications that only need pipeline scheduling atop custom data structures. Pipellow simply requires users to specify the pipeline structures (e.g., the number of parallel lines) and pipe callables, and provides a scalable pipeline API for users to flexibly define the pipeline scheduling frameworks with dynamic structures based on their specific needs.

Existing pipeline scheduling algorithms. typically co-design task scheduling and buffer structures to strive for the best performance. For instance, oneTBB [1] defines a per-stage buffer counter to synchronize data tokens among stages and parallel lines, coupled with a small object allocator to minimize the data allocation overhead; GRAMPS [70] designs a buffer manager with per-thread fix-sized memory pools to dynamically allocate new data and release used ones; FastFlow [4] designs a lock-free queue with a mechanism to transfer data ownership between senders and receivers, but
this method can incur imbalanced load and requires non-trivial back-pressure management; HPX [46] counts on a channel data structure and standard future objects to pass data around tasks, but the creation of share states becomes expensive when the pipeline is large; Cilk-P [50] employs per-stage queues coupled with two counter types to track static and dynamic dependencies of each node, but it targets on-the-fly pipeline parallelism, which is orthogonal to our focus; FDP [72] proposes a learning-based mechanism to adapt scheduling to an environment, but it requires expensive runtime profiling that may not work well for highly irregular applications like CAD. Pipelofow leverages C++ simple atomic operations and assigns every pipe an atomic variable denoting the dependency. Since there is no data synchronization involved, the scheduling algorithm of Pipelofow is lightweight and efficient. In terms of load balancing, most pipeline schedulers leverage work stealing, which has been reported with better performance than static policies [6, 23, 50, 52, 66, 70, 71]. However, for some special cases, such as fine-grained load-imbalanced pipelines, static policies perform comparably. For example, Pipelight [64, 65] implements a load-balancing technique based on two static scheduling algorithms, DSWP [67–69] and LBPP [47]; Pipelite [63, 65] and URTS [62, 65] introduce dynamic schedulers using ticket-based synchronization and directive-based model language for linear pipelines, respectively. Although, in some special cases, work stealing [53] may not give the best runtime performance, Pipelofow and the most framework software still adopt this algorithm as it has the best performance in most applications. While co-designing task scheduling and buffer structures has certain advantages for data-centric pipeline (e.g., data locality), the cost of managing data can be significant yet unnecessary, especially for applications that only exploit task parallelism in pipeline.

6 CONCLUSION

In this paper, we have introduced Pipelofow, an efficient task-parallel pipeline programming framework to explore pipeline parallelism in applications. We have introduced a simple yet efficient scheduling algorithm based on our work-stealing runtime with dynamic load balancing. We have evaluated the performance of Pipelofow on a micro-benchmark and an industrial application. For example, in a VLSI static timing analysis workload that adopts pipeline parallelism, the Pipelofow’s implementation is up to 110.33% faster than the oneTBB’s implementation. Our future plans are to 1) apply Pipelofow to other applications than CAD applications to bring interdisciplinary ideas to the parallel computing community and 2) extend Pipelofow to task-parallel GPU computing platforms [11, 12, 43, 55–57] and distributed environment [28, 31, 42].
